Acknowledgments: We would like to thank the Coleman Fung Institute of Engineering Leadership, the Harvard Business School Department of Research, and the National Science Foundation (Grant #0830287 and #0965341) for supporting this research. Errors and omissions remain ours (though we ask that you bring them to our attention). We would like to express our gratitude to Jerry Marschke for providing his inventor dataset for our algorithm checks and Jim Bessen and the NBER for providing access to their assignee names database. This paper draws much material and replaces an earlier unpublished paper, by Lai, D'Amour, and Fleming, titled, "The careers and co-authorship networks of U.S. patent-holders, since 1975."

Disambiguation and co-authorship networks of the U.S. Patent Inventor Database (1975-2010)

Abstract: In order to uniquely identify inventor careers, we describe an iterative enhancement to the “Author-ity” disambiguation algorithm (Torvik et. al, 2005; 2009) and its application to all inventor names in the U.S. utility patent database, 1975-2010. The iterative nature of the algorithm refers to a successive blocking mechanism that expands the candidate match space while maintaining scalability. The paper provides an overview of the disambiguation method, assesses its accuracy, characterizes the resulting dataset by basic descriptive statistics, and calculates network measures based on co-authorship and collaboration variables. It illustrates the potential for large-scale innovation studies across time and space with visualizations of inventor mobility across the United States. The complete input and results data from the disambiguation are available at (<http://dvn.iq.harvard.edu/dvn/dv/patent>); revised code is available at (<https://github.com/funginstitute/downloads>); visualizations of inventor mobility are at (http://atticus.berkeley.edu/guanchengli/arcc/index_w.php).

Keywords: disambiguation, patents, networks, inventors, careers.

1. Introduction

Relatively complete though raw patent data for the United States became widely available in the 1990s. While these data enabled research in the fields of technology and innovation, the publication of a curated dataset by the National Bureau of Economic Research (NBER) gave a much broader set of researchers access to the patent data (Hall et al., 2001). The NBER effort reduced the barrier to entry by making patent data accessible to a larger community of researchers that lacked the resources and hardware or programming skills to access the data. The original NBER database included inventor names, firm and state level data but did not identify unique inventors over time.

Uniquely identifying inventors presents two non-trivial challenges. First, the United States Patent Office (USPTO) does not require consistent and unique identifiers for inventors. A simple example: the last author of this paper is listed as Lee O. Fleming on patent 5,136,185 (Fleming, 1992) but as Lee Fleming on patent 5,029,133 (Fleming, 1991). Both inventors work for Hewlett Packard, both invent semiconductor circuits, and both live in Fremont, California – without personal knowledge, with what confidence could we assume that this is the same inventor? Moving directly into the second challenge, could we repeat this process for millions of inventors? Accurate and automatic disambiguation of the entire patent record requires careful algorithm design to ensure scalability and, even then, significant computational resources to ensure feasibility. For example, the naïve and brute force approach to compare all pairwise inventor-patent records is not feasible at full scale for any but perhaps the most powerful computers in existence.

In recent years there has been a flurry of activity surrounding the problem of name ambiguity in bibliographic records such as journal and conference paper collections (reviewed by Smalheiser and Torvik, 2009). Of particular note, and strong motivation for this paper, recent work has highlighted the pitfalls of poor or simplistic author disambiguation; for example: Raffo and Lhuillery (2009) demonstrate differences in econometric inferences, Diesner and Carley (2009) show differences in entity resolution and relationships in newspaper corpora, and Fegley and Torvik (2012) illustrate dramatic distortions in social networks due to non-existent or poor disambiguation. Due to space constraints, we will not make similar comparisons here, but take this cautionary research seriously and recommend the reader to this literature.

1.1 Existing work and contribution

Our paper contributes 1) an application of the Torvik-Smalheiser disambiguation algorithm to the US utility patent database, 2) an iterative blocking scheme that expands the match space of this algorithm while maintaining scalability, and 3) a database of inventor careers and social networks that results from the application of these algorithms. The work builds directly on prior efforts by a variety of innovation researchers (Fleming and Juda 2004; Singh 2005; Trajtenberg

et al., 2006; Raffo and Lhuillery 2009; Carayol and Cassi, 2009; Lai et al., 2009; Pezzoni et al., 2012). The database provides unique identifiers for each patent’s inventors across the entire time period. It also provides social network measures by each inventor, by three-year periods from 1975 to 2010. To illustrate applications of the data, we provide movies of inventor mobility across large U.S. states since 1975 and an inventor-scientist career linkage to PubMed (Torvik and Smalheiser 2009). The algorithms and code are made public to encourage further development and improvement by the community of patent and innovation investigators. In addition to improved disambiguation, the Harvard Dataverse Network (DVN) website provides a network interface that enables a researcher to subset the co-authorship networks of inventors.¹ Output formats support both regression analysis and graphical network programs.

Office (USPTO) weekly publications.² The data preparation step generates four primary datasets containing the relevant inventor, patent, assignee, and classification data that will be used in the inventor disambiguation process. These datasets are consolidated and then fed into the disambiguation algorithm that outputs the inventor career database.

1.2 Disambiguation Algorithm

Many existing disambiguation algorithms cluster records by calculating similarities between pairs of records, then grouping together sets of records that exceed arbitrary thresholds, or by assigning ad hoc weights to record attributes such as inventor name, assignee, technology class, co-inventors, etc. in order to determine a unitless match score (Fleming and Juda, 2004; Trajtenberg et al., 2006; Singh 2005; Lai et al., 2009). Above a predetermined threshold, two records would be declared a match. This weighting scheme is then tuned to maximize results with a hand-curated dataset.

However, manually optimizing a disambiguation scheme is susceptible to a number of problems that our machine learning approach mitigates. The first is model-dependence; the linearly weighted combination of the similarity scores assumes independence, despite clear and non-trivial interactions between certain feature similarities. For example, if two records match on assignee, but the assignee is large and works in multiple fields, the technology class overlap can have a large impact on how the assignee match ought to be considered (for a small firm, for whom all patents are in the same technology, class overlap may add little information, but for a large firm, it may add a great deal). Linear specifications could handle these dependencies by introducing interaction terms, but this model-selection problem would be cumbersome and lead to non-linearities whose predictive accuracy would be hard to assess.

The second problem with manual optimization is that the dataset being used to train the weights, no matter how accurate, typically represents a small, biased sample. Inventors in these gold-standard datasets tend to belong to the same communities (e.g. the BIIS dataset in Trajtenberg et al., 2006, or our dataset, based on the Marschke survey of academic inventors, see Gu et al., 2008) or tend to be more prolific than average, making them more visible to researchers doing a manual survey. Despite the best efforts by researchers, hand-curated datasets are often incomplete; many inventors do not maintain a complete and updated (let alone published) list of patents that they have invented. Even carefully sampled and executed surveys remain vulnerable to bias, for example, some inventors remain difficult to contact (e.g., the deceased). While still

² Some of the early NBER data are missing and are supplemented by the 1998 Micropatent CD product (<http://www.micropat.com/static/index.htm>). We would like to acknowledge the donation of these data from Corey Billington and Ellen King of Hewlett-Packard. This completes approximately 70,000 gaps in data for records from 1975-1978.

useful for verification, these biases make hand-curated datasets a poor choice for training a probabilistic model.

Finally, valuable information is lost when assigning each pair of records a unitless match score, rather than a probability having a natural interpretive value. Determining such match scores requires judgment and domain-specific experience investigator's part. In contrast, probabilities can be estimated by measuring the statistical properties of the data.

Following the work on PubMed by Torvik et al., (2005), and Torvik and Smalheiser (2009), and on patents by Carayol and Cassi (2009) we avoid ad hoc decisions and mitigate these limitations by:

- 1) Training a probabilistic model that a) assumes only multidimensional order and therefore captures non-linear and interaction effects among the predictive features, b) allows for correcting transitivity violations among triples of inventor-patent instances based on principles of probability theory, c) provides a natural likelihood-based framework for clustering.
- 2) Training with large, diverse, and automatically generated training sets of highly probable matches and non-matches sampled across the entire dataset so that selection bias, training variance, and manual effort is reduced.
- 3) Using intentionally generic predictive features so that the trained model can be applied to new data.

Technical details can be found in the references, and we encourage the interested reader to consult them. Our intent here is to broadly characterize the model and algorithm to a non-technical audience, so that innovation scholars might make more effective use of the disambiguated data.

1.3 Precís

The second section of the paper ("*Overview of dataset preparation*") provides an explanation on how the inventor dataset is created; the third section ("*Disambiguation: overview, theory, and implementation*") provides a non-technical overview and explanation of the disambiguation processes; the fourth section ("*Results and accuracy metrics*"), describes how we report results and accuracy; the fifth section ("*Disambiguated data and illustrative applications*") illustrates applications of the data. Appendices include patent data descriptions, listing of data and results distributed through the Harvard Dataverse Network and schemas used in and produced by the disambiguation.

2. Overview of dataset preparation

Dataset preparation consists of obtaining patent and patent-related data from primary and secondary sources, parsing raw patent data as needed, cleaning both patent and secondary source data, and consolidating the parsed and cleaned inventor and patent data into a single database containing inventor-patent instances, or records, to be disambiguated.

Figure 2: Source files for disambiguation process.

2.1 Primary data sources

The final inventor, assignee, inventor, patent and classes datasets were built using primary data sources from the USPTO and the NBER. The USPTO makes up-to-date patent data available on their public web resource³ through collaborations with the European and Asian patent offices. The weekly data file is a concatenated list of granted patents, where each patent is represented by an XML document. The NBER patent database contains patents granted from 1975-1999 and is publicly available⁴. Since the patent office only began automating data storage in 1975⁵, we are

utilizing information from 1975 onwards. To the best of our knowledge, there is no freely available and comprehensive computer database containing U.S. inventor information before 1975, though bulk download of images and OCR text (of variable quality) files are available.⁶

2.2 Secondary data sources

In addition to the primary data sources, we merged in data from secondary data sources to help identify inventors. These secondary data sources include the USPTO CASSIS dataset⁷, the National Geospatial-Intelligence Agency country files⁸, the US Board on Geographic Names⁹ and NBER File of Patent Assignees.¹⁰

When a patent is granted, the USPTO assigns multiple alphanumeric codes to classify the technology. As technology advances, the USPTO creates new classifications and updates previously coded patents. These classification changes are indicated in CASSIS, a dataset that is updated bimonthly. Classifications reflect the November 2009 concordance. Geographic metrics are sourced from public databases such as the National Geospatial-Intelligence Agency and the US Board on Geographic Names, current through 2009. Since assignees are often public firms, we leverage the NBER Patent Data Project (PDP).¹¹ Through a combination of the NBER PDP data and heuristic string matching procedures, we have incorporated NBER's unique assignee identifier, PDPASS, into our input dataset.¹²

⁵ NBER provides limited data from 1963-1999 but only provides inventor data from 1975-1999. Since inventor information is necessary in our disambiguation algorithms, we have only matched inventors to patents granted after 1975. Further information about the inventor dataset can be found at: <http://www.nber.org/patents/inventor.txt>.

2.3 Preparing the inventor dataset

Figure 3: Preparing patent data for disambiguation.

Figure 3 provides a schematic of the data preparation process. The initial step parses the raw data input. In order to minimize redundancy, several smaller datasets were created and joined together using unique patent and inventor identifiers rather than generating one large dataset containing all unique combinations of patent information. USPTO patent data contain 60+ fields of information. If we were to restrain our data into one primary dataset, unique permutations of each field would be difficult to manage. For example, many patents contain several inventors (INV), several classifications (CLS) and several citations (CIT). At the very minimum, a dataset would require $INV \times CLS \times CIT$ records of data, many of which would remain empty.

The smaller, independent datasets consist of assignees, citations, patent technology classes, inventors and patents. The data within the independent datasets are further cleaned before being consolidated for disambiguation. Cleaning includes removing excess whitespace, standardizing date formats and similar tasks. Consolidation includes adding location and assignee data, which are matched between the primary and secondary data sources to merge longitude, latitude, and assignee identifier information within the inventor and patent datasets. The cleaned, consolidated data comprise the input dataset for the disambiguation process.

3. Disambiguation: overview, theory, and implementation

The basic challenge in studying inventor careers from the raw patent data is determining which patents belong to the same inventor career. The patent data include unique identifiers for each patent, but not for inventors, so clustering of patents by distinct inventors on a large scale requires a procedure that can cluster together patents by the same inventor and distinguish them

from patents by other inventors with the same or similar name. The process of clustering together likely distinct inventors is called disambiguation. Figure 4 illustrates our disambiguation process, with iterative blocking.

Figure 4: Steps in the iterative disambiguation process.

3.1 Overview of terms and method

The raw data in our disambiguation are not patents per sé, but patent authorships, or what we call *inventor-patent instances*. Each instance corresponds to a name appearing on a patent – for example, a patent with three authors contributes three inventor-patent instances. The core of the disambiguation algorithm is to consider all pairs of these inventor-patent instances and to determine whether or not they belong to the same inventor career. The primary unit of analysis in the core algorithm is therefore pairs of inventor-patent instances, also known as *inventor-patent pairs* or co-authorship pairs.

Viewed in this way, the disambiguation problem boils down to a *classification* problem, where we wish to label inventor-patent pairs as *matches* – that is, pairs where both inventor-patent instances come from the same career – or *non-matches*. Classification is one of the fundamental problems in statistical machine learning, and has received wide treatment (See for example *Elements of Statistical Learning* by Hastie et al or *Pattern Recognition and Machine Learning* by Bishop). A classification algorithm or *classifier* takes in a set of attributes or measurements associated with an object and, based on a set of previously “*learned*” representative examples, uses these attributes to label the object with a class. In this case, the objects are inventor-patent pairs; the attributes are similarity scores obtained by comparing the entries associated with each inventor-patent instance in the pair, for example the similarity in their names, or the distance between their addresses; and the class is an inventor career.

For our purposes, we apply a specialized implementation of a general technique known as a *Naïve Bayes Classifier* to classify inventor-patent pairs as matches or non-matches. This technique is well studied, and despite its simplicity, performs surprisingly well in real problems (Hastie et al 2001, Bishop 2006, Lewis 1998, Rish 2001, Zhang 2004). The classifier is *naïve* because it assumes independence between certain sets of attributes, and it is *Bayesian* because it uses Bayes' rule to learn the relationship between attributes and class in the example set and then generalize it to the whole database.

The general procedure proceeds as follows. We begin by defining a representation of the attributes of an inventor-patent pair that we call a *similarity profile* (essentially selecting a subset of characteristics to compare and defining how to compare them). Once we have settled on a representation, we obtain *training sets*, or sets of inventor-patent pairs whose labels are known so that the classifier can learn what attribute-class relationships to generalize (essentially selecting sets of pairs that are extremely likely to be the same - or different - inventors). We generate these training sets automatically using a procedure that minimizes bias by assuming independence between different parts of the similarity profile. Using these training sets, we learn the *likelihood* that a given similarity profile was generated by a match set or non-match set. We then compute similarity profiles for inventor-patent pairs in the larger database, and use the likelihood values to determine whether there is enough evidence to declare a pair of inventor-patent instances a match. Finally, we resolve any conflicts that arise in the match and non-match classifications between different inventor-patent pairs, and convert these into clusters of inventor-patent instances that represent full inventor careers.

To reduce computational effort, we first *block* the records by predetermined criteria such as matching exactly on first and last names (in other words, rather than considering all pairwise patent instances in the entire database, we only consider likely matches). We then compute the similarity profile and consequently the match probability. Within each block we then iteratively develop working clusters of each inventor's patents. Repeated rounds of agglomerative clustering terminate when the log-likelihood of the clustering solution hits its maximum. To avoid confusion, *disambiguation* refers to the entire "who's who" process, while *matching* refers to the direct comparison of records to determine unique inventors.

Torvik and Smallheiser pioneered this classification approach to the disambiguation problem. We refer to the whole procedure, including similarity profile construction, automatic training set generation, technical constraints on the training likelihoods, and simple blocking heuristics employed to reduce computation as the *Torvik-Smallheiser algorithm*. Our contributions are an iterative blocking scheme (defined in Sections 3.4 and 3.5), and the application of this algorithm to the US patent record.

3.2 A Bayes theorem classifier for disambiguation

The core statistical idea in the Torvik-Smallheiser algorithm is the application of Bayes' theorem to derive the probability that an inventor-patent pair is a match given its similarity profile.

Formally, if we define M to be the event that an inventor-patent pair is a match and N to be the event that it is a non-match, we can use Bayes' theorem to write the probability of M given that we observed a similarity profile x as

$$P(M|x) = \frac{P(x|M)P(M)}{P(x|M)P(M) + P(x|N)(1 - P(M))}. \quad (1)$$

Here, $P(M|x)$, the *posterior probability of a match*, is the quantity of interest. $P(x|M)$ and $P(x|N)$ are the *likelihoods of the similarity profile* given that the pair is a match or a non-match, respectively. $P(M)$ is the *prior probability of a match*, and must be specified by the user.

It is often easier to work with the *posterior odds of a match*, which have a one-to-one relationship with the posterior probability:

$$\frac{P(M|x)}{1 - P(M|x)} = \frac{P(M)}{1 - P(M)} \frac{P(x|M)}{P(x|N)}. \quad (2)$$

The key factor here is the second fraction on the right-hand side that is called the *likelihood ratio of a match*, and quantifies the evidence for a match versus a non-match. Intuitively, the posterior odds of a match are the prior odds multiplied by this likelihood ratio. We call the likelihood ratio the *r-value*, defined as

$$r(x) = \frac{P(x|M)}{P(x|N)}. \quad (3)$$

The *r-value* is determined directly from the training set, simply by calculating the proportion of times that the similarity profile x appeared in the match set and the non-match set and taking their ratio. To account for noise that can arise from rare similarity profiles, we modify these raw values slightly to enforce monotonicity constraints and to interpolate or extrapolate missing *r*-values (Torvik et al. 2005), a procedure discussed in the section on training sets (Section 3.6).

Eq. 2 is easily converted back into an expression for $P(M|x)$, so that we can write the quantity of interest in terms of the *r-value* and prior information:

$$P(M|x) = \frac{1}{1 + \frac{1 - P(M)}{P(M)} \frac{1}{r(x)}}. \quad (4)$$

The prior probability of a match $P(M)$ is specified *a priori* based on, for example, the size of the block under consideration (for example, a larger block makes a match less likely). We discuss prior probabilities in Section 3.7.

Next, we provide a detailed but less technical overview of each aspect of the disambiguation algorithm in turn, providing citations when appropriate for readers interested in technical detail.

3.3 Inventor-patent instance data

The unit of analysis in our disambiguation is an *inventor-patent instance*, also referred to as an *inventorship*, each corresponding to a record in the input dataset. Each record contains *attributes* used for disambiguation, such as the inventor’s first and last names, the inventor’s latitude and longitude, the patent assignee, and others as explained below. Each inventor-patent instance occurs only once. In contrast, a patent may appear multiple times, once for each inventor listed on the patent. For example, disambiguating a patent with three inventors would result in three inventor-patent instances, hence three records. The input dataset was created by merging data from the relevant databases to create a table containing over 8 million inventor-patent instances.

An inventor's name is the most distinguishing attribute. In the raw dataset, the inventor name is split into first name (with middle name, when present) and last name (with suffix, when present). We define a full name as having both first and last name present, which is available for 99.99% of records. Having a full name for disambiguating patent inventors is a major advantage over disambiguation of journal and conference paper collections, which often lack author’s first names.

When the USPTO issues a patent, the original owner of the patent, which is most often the employer of the inventor (Singh and Fleming, 2010), is listed as the *assignee* on the patent grant. The assignee’s name would ideally be enough to identify the firm that holds the patent, but problems arise from misspellings, from different forms of the same company's name and from subsidiaries having completely different names from the parent. For example, consider “IBM” versus “International Business Machines”, the same assignee with different forms of the company name.

A combination of address features (city, state, country and zip code) were matched against public geographic databases from the National Geo-spatial Intelligence Agency to extract longitude and latitude of inventor’s physical location. Using geographic coordinates permits calculating distances between inventors where simple address string similarity does not accurately capture the “closeness” of two different addresses. Street addresses were not available for all records and were not used. Converting the variety of geographical data fields to a longitude and latitude makes the comparison more robust to missing data (for example, all zip codes are not available).

Each patent also has a list of technology classes and co-authors. These categories provide important information about the inventor's area of expertise and co-authorship network, respectively. For simplicity and computational efficiency, shared co-inventor and technology classes are truncated at the first four primary classes and co-inventors. Table 1 illustrates the fundamental challenge of disambiguation: given the attributes, are these patents invented by the same person? Further examples will develop how we answer this question in more detail.

ID	Patent	Firstname	Middlename	Lastname	Coauthor	Class	Assignee
P1	7285077	Matthew	NONE	Marx	NONE	482	NONE
P2	7321856	Matthew	Talin	Marx	MANY	704/379	Microsoft
P3	5995928	Matthew	T	Marx	ONE	704	Speechworks

Table 1 Example patents for inventors named Matthew Marx.

3.4 Blocking

In principle, we would like to classify each inventor-patent pair in the database as a match or non-match. However, exhaustive pairwise comparison requires quadratic run time. Because each inventor-patent instance must be compared with every other inventor patent instance, an exhaustive comparison of every pair of 8 million records in the patent database would require over 32 trillion comparisons, making the full problem computationally infeasible. One popular approach for making classification based on pairwise computation feasible is blocking the records first, and restricting comparisons within blocks (On et al., 2006, Bilenko et al., 2006, Herzog et al., 2007, Smalheiser and Torvik 2009, Reuter and Cimiano, 2012).

We block by partitioning all inventor-patent instances into high-risk groups, where almost all matches are assumed to occur within a group. This partition is defined by crudely summarizing all inventor-patent instances with a *block identifier*, and then bucketing all records with the same block identifier together. For example, an early iteration may block by complete first and last names, resulting in a blocking identifier composed of SMITH, JOHN. Later iterations may define coarser, and thus more permissive, block identifiers consisting of different combinations of truncated parts of first and last names, e.g., SMITH, J.

Choosing the feature set for any particular blocking scheme is a difficult balancing act. On one hand, creating blocks that are too big does little to reduce the quadratic run time. On the other hand creating blocks that are too small can rule out correct matches by assigning patents from the same inventor to different people. To deal with this time/accuracy trade-off, we developed a novel blocking scheme through iterative application of the Torvik and Smalheiser (2009) algorithm, refining the blocking rule with each iteration.

3.5 Pairwise comparison within each similarity profile

Classifying inventor-patent pairs requires defining a comparison function C that takes two sets of record entries and returns an n -dimensional similarity vector (or profile) $x = (x_1, x_2, \dots, x_n)$ between inventor-patent instances. Each feature x_i of the similarity profile is a positive integer resulting from comparing two records, with higher values corresponding to greater similarity between respective features. Our current feature set includes: first name, middle initial, last name, inventor location, assignee, number of shared technology classes, and number of shared co-inventors.

For our example, consider the following comparison function C defined on seven features, where each feature-wise comparison returns a value in the indicated range:

1. First name [0..4]: value 0 when names are completely different, value 4 when lexicographically identical, with intermediate values determined by degree of similarity between the names being compared.
2. Middle name [0..3]: handled similarly to first names, using an appropriate comparison function to account for presence or lack of presence of a middle name.
3. Last name [0..5]: handled similarly to first and middle names, with more nuanced treatment of the last name in terms of comparison.
4. Coauthor [0..6]: number of common coauthors, where more than 6 common coauthors is set to a maximum value of 6.
5. Technology class [0..4]: values from 0 to 4 representing the number of shared technology classes between the two records being compared, where 4 is defined as the maximum feature value when four classes are in common between the records.
6. Assignee [0..6]: The assignee feature incorporates both the assignee name and the assignee number, when available. Value 0 when both name and number are available and different; value 1 when one or both of the records are missing assignee information. Values from 2-5 report similarity in name, with value 6 indicating an exact match on an assignment number.
7. Location [0..5]: 0 when inventors not in the same country; for inventors in the same country, values ranging from 1 to 5 are determined from distance computed from latitude and longitude.

We can use this function to construct the similarity vectors for the inventor-patent instances containing the name “Matthew Marx” (from Table 1). The pairwise comparison of each row of Table 1 results in the following similarity vectors:

$$C(P_1, P_2) = (4, 1, 5, 0, 0, 1). \quad (5a)$$

$$C(P_1, P_3) = (4, 1, 5, 0, 0, 1). \quad (5b)$$

$$C(P_2, P_3) = (4, 3, 5, 0, 1, 0). \quad (5c)$$

The composition of the similarity profile depends on the classifier chosen for a particular round. See, for example, disambiguation Round 3 in Table 3 below, where all of the above features are used for the classifier, versus disambiguation Round 2 where the location is incorporated instead of the technology class. Regardless of the composition of the similarity vector, the core task remains mapping these profiles to the probability of a match (discussed in section 3.8 below).

3.6 Training sets

The key hurdle in converting the disambiguation problem into a classification problem is obtaining training sets that are both large and unbiased; if this can be done, then disambiguation becomes a machine-learning learning problem. Making the training set large requires that we construct these training sets automatically; making them unbiased requires that we make reasonable assumptions about independence of similarity profile entries.

Our approach is to automatically generate training sets of highly probable matches and non-matches. We first divide the set of features into two mutually exclusive subsets that are assumed to be independent in their effect on the match probability. The current specification divides the seven features into two groups: name features (first name, middle initials, and last name) and patent features (inventor location, patent assignee, technology class, and co-inventors). To generate a set of highly probable matches for the study of name features, we selected pairs of records that shared two or more co-inventors and two or more common classifications of the patents. Similarly, to generate a set of highly probable matches for the study of patent features, we selected pairs of records where the inventor name was rare and matched exactly.

Since the training set based on names is created through exhaustive selection of pairs of rare names, any overrepresentation of a specific rare name (i.e. an extremely prolific rare-name inventor) could bias the training set. Misspellings also show up as extremely rare names, and must be identified and disregarded. To determine which names to use, we selected unique name combinations of rare first and last names that occurred more than once and less than four times. For example, we observe only one example of Kia *Silverbook*, but many examples of Kia *Silverbrook*. In comparison, we also observe many John Smiths, but given that both John and Smith are very common names, we reject John Smith as a common name. We followed

analogous procedures to create non-match training sets. Table 2 summarizes conditions for generating training sets.

	Match Set	Non-Match Set
Learn patent name attributes	Pairs of matched full inventor names defined as rare with respect to all inventor names.	Pairs of non-matching full inventor names chosen from rare name list.
Learn name patent attributes	Pairs sharing more than 1 common coauthors and technology classes.	Pairs of inventors from the same patent.

Table 2: Description of training sets, defining how record pairs were selected, and which feature sets they were intended to train.

The relative frequency with which a similarity profile appears in both match and non-match training sets is used to calculate its r -value (Eq. 3), which is then stored in a lookup table.

Because they are estimated quantities, the raw r -values can be noisy, and need to be smoothed, though smoothing requires some assumptions. One reasonable assumption is that inventor-patent pairs with greater similarity ought to have greater match probability, however this can be violated if certain similarity profiles are rare. To remedy this problem, we follow Torvik et al. (2005), and define a *product order* between similarity profiles x and y where we say x is greater than y if and only if every entry of x is greater than or equal to every entry of y , or formally, $x \preceq y \Leftrightarrow x_i \leq y_i \forall i = 1, 2, \dots, n$, where n is the dimension of the similarity profile. We use this ordering to explicitly impose a *monotonicity constraint*, such that for any two similarity profiles x and y , if $x \preceq y$ then $P(M|x) \leq P(M|y)$. It can be shown that this is equivalent to imposing monotonicity on r -values: $P(M|x) \leq P(M|y) \Rightarrow r(x) \leq r(y)$.

When profile A is greater than profile B , each element in A is equal to or greater than the corresponding element of profile B , and A must map to a higher match probability than B . Consider the similarity profiles (Eqs. 5a, 5b, 5c) constructed from Table 1 using inventor name “Matthew Marx.” Let $A = (4,3,5,0,1,0)$ and $B = (4,1,5,0,0,0)$. Comparing element-wise, $i = 1, 2, \dots, 6$; $a_i \in A, b_i \in B, a_i \leq b_i$, thus $A \leq B$. Using r -values obtained from the actual disambiguation, for profile A , $r = 0.593733$, and for profile B , $r = 0.000472872$. (As it turns out, similarity profile A indeed does reflect the same individual, and similarity profile B does not.)

We use the monotonic ordering assumption to smooth the r -values that are observed in the training set and to interpolate or extrapolate when new similarity profiles that did not appear in the training set are encountered in the larger database. We perform this smoothing by finding the

set of monotonic r -values that has the minimum weighted squared distance from the raw r -values, where the weights are proportional to the number of times the corresponding similarity profile appeared in the training sets. This optimization problem can be solved using quadratic programming (Torvik et al., 2005).

Unfortunately, a small or zero value in the denominator can greatly influence the r -value. In order to dampen the influence of extreme ratios, we apply a Laplace correction equal to 5 when one of the similarity profiles has more than 100 occurrences. The value 5 follows Torvik et al.'s (2005) experience in disambiguating the similarly sized Medline data; the value 100 was determined by examining the match (M) and non-match (N) similarity profiles to catalog the magnitude of M/N ratios. Comparing the numbers in between a typical vs. outlier influence on r -values indicated ~ 100 similarity profiles that required a Laplace correction.

Training sets, whether based on inventor names, technology class, co-inventor or the like depend strongly upon the particular blocking rule. Hence, after blocking and before each round of disambiguation, training sets are recreated and a new r -value lookup table is built, specific to each round of blocking.

3.7 Prior probabilities

The prior match probabilities $P(M)$ for pairs within each block are determined in two steps. In blocking rounds after the first, when working clusters have been defined previously, we use the ratio of within-cluster pairs in a block to the total number of pairs in that block to compute an initial value for $P(M)$. The initial blocking round starts each cluster in the block with only one record and computes the same ratio (essentially the inverse of the number of pairs in the block, assuming no pre-consolidation for exactly similar fields, as described below).

We then adjust this initial prior probability for each block according to the frequency of each part of its block identifier, *i.e.*, it is penalized if and only if all parts of the block are both very common; otherwise, it gets augmented for each part of the block identifier. In our current engine, the factor of modification is the logarithm of the ratio of the maximum occurrence of a block identifier to the occurrence of the current block identifier. In other words, the prior probability decreases, when identifiers are common, because greater skepticism of a match is warranted.

3.8 Inventor-patent pair matching and iterative clustering into careers

Given a mapping from every possible similarity profile to its likelihood ratio r , calculating the probability that any two inventor-patent pairs match becomes relatively simple. Before comparing the two records, the prior match probability $P(M)$ is calculated based on the type of blocking that was performed. The two records are compared field-wise to generate a similarity

profile. The probability of a match, given an observed similarity profile and prior probability, is then calculated from Equation 4.

These pairwise probabilities must then be grouped by inventor, in order to collect all the patents in each career. We accomplish this grouping with repeated iterations of working or potential clusters. A cluster consists of 1) the inventor's patents, 2) a *cohesion* value, and 3) a *cluster representative record*. Cohesion is the arithmetic average of some of the pairwise comparison probabilities among the members. The cluster representative record has the most attributes in common with all the records in the cluster.

The iterative clustering process follows each round's matching. In the very first round of blocking, working clusters begin at most as the individual inventor-patent pairs (with the exception of the pre-processing, described below). In subsequent rounds, working clusters begin based on the previous round's last clusters. First, a similarity profile is computed between cluster representatives, followed by the *r*-value lookup for the similarity profile, after which the final match probability of the two representatives is calculated. If the match probability of the representatives does not pass a minimum threshold (empirically set at 0.3 to minimize run time, based on the observation that no final clustering ever occurred beneath that), it is assumed that the clusters are not of the same inventors and that running the full comparison process would be a waste of time. This prescreening step can significantly accelerate the overall disambiguation process.

If the comparison between working cluster representatives passes the minimum threshold, exhaustive comparisons between members of the two clusters are performed, along with an effective comparison count based on the size of the two clusters. The introduction of the effective comparison count is to allow clusters representing inventors of high mobility to merge. Instead of having to meet the requirement that the average of all comparisons between members in the two clusters surpasses a certain threshold, the two clusters need only to pass the threshold for the average of the maximum effective comparison count number of probability values among all the exhaustive comparisons. If the effective comparison count average is greater than the threshold, the two clusters will merge, and the cohesion value of the new cluster is set to the effective comparison count average, after which a new representative can be determined.

A sequence of monotonically decreasing thresholds is set, with the expectation that more similar clusters should agglomerate first. If the comparison of two working clusters yields a probability greater than a given threshold, the two clusters will consolidate into a larger working cluster, and the within-cluster density and cluster representative are updated. The iterative grouping within a block starts again with a lower threshold if no more working cluster representative pairs qualify for consolidation under the current threshold. The loop continues until all thresholds are passed, signaling the end of the disambiguation of the block based on its current blocking mechanism.

These working clusters are then fed into the next round with different blocking rules and possibly different similarity profiles. The working clusters at the end of the last round become the final result of the inventor disambiguation.

3.9 Additional pre and post-processing steps

To improve performance, before the first round of the disambiguation, we consolidate without disambiguation those records which have multiple identical features, i.e. first name, middle name, last name, city, state, country, assignee. While such pre-consolidation works well in most cases, it does cause problems for East Asian names (Japanese, Korean, and Taiwanese), primarily because many such inventors share common and identical names, and work for big firms in developed locations. However, it should be noted that such inventors remain difficult to identify even with the complete disambiguation engine. Following each round of disambiguation, the first names, middle names, and last names of cluster representatives are compared using heuristic Jaro/Winkler string comparison (Herzog et al., 2007, Chapter 13). If the string comparison indicates high similarity (> 0.95) in all the three fields, the two relevant clusters merge.

A summary of the passes made over the data is provided in Table 3. On each subsequent pass, we decrease the blocking threshold; because of the record consolidation that had been applied after the previous pass, we can maintain reasonable runtimes. This allows exploration of more comparisons than would be feasible in the single-blocking scheme. Note especially the steep drop in the number of records after the first few rounds, allowing more permissive blocking.

Run #	Type	Blocking rule	Similarity Profile	Count
0	Preconsolidation	Exact first name, exact middle name, exact last name, city, state, country, assignee	N/A	4.51 million
1	Consolidated	First name without space, last name without space	First name, middle name, last name, city	3.09 million
2	Consolidated	First name without space, last name without space	First name, middle name, last name, coauthor, assignee, geographical location	2.84 million
3	Consolidated	First name without space, last name without space	First name, middle name, last name, coauthor, class, assignee	2.82 million
4	Consolidated	First 5 characters of first name without space, first 8 characters of last name without space	First name, middle name, last name, coauthor, geographical location, assignee	2.80 million
5	Consolidated	First 3 characters of first name without space, first 5 characters of last name without space	First name, middle name, last name, coauthor, geographical location, assignee	2.75 million
6	Consolidated (the lower bound)	First name initial, first 5 characters of last name without space	First name, middle name, last name, coauthor, geographical location, assignee	2.70 million
7	Consolidated	First name initial, first 3 characters of last name without space	First name, middle name, last name, coauthor, geographical location, assignee	2.67 million
8	Consolidated (lower bound)	First name initial, first 2 characters of last name without space	First name, middle name, last name, coauthor, geographical location, assignee	2.66 million

Table 3: Iterative blocking and consolidation scheme.

4. Results and accuracy metrics

Our goal is to properly capture and assign all of an inventor’s patents to a single and unique inventor number. Analogous to type I and II error, however, no disambiguation procedure will provide perfect identification. A variety of terms have been used to label incorrect matching; following Torvik and Smalheiser (2009) we use measures of lumping L and splitting S :

$$L = \frac{f_p}{t_p + f_n}, \quad (6a)$$

$$S = \frac{f_n}{t_p + f_n}, \quad (6b)$$

Lumping occurs when distinct inventors are incorrectly identified as one. *Splitting* occurs when one inventor is identified as multiple inventors. In the present method, two or more inventors in the same cluster constitutes a lumping error; one inventor in two or more clusters constitutes a splitting error.

Lumping and splitting correlate negatively: if one goes down the other goes up and vice-versa. We therefore generated two different datasets, one which attempts to capture inventor careers in their entirety at the cost of occasionally lumping distinct inventors together, and the other of which attempts to ensure that each cluster corresponds to a distinct inventor at the cost of occasionally splitting a single inventor into multiple careers.

The two datasets permit researchers to choose, depending on the substantive costs of lumping or splitting. The *lower-bound* disambiguation results from an additional (and last) round of disambiguation. We define the penultimate disambiguation as the *upper-bound*, done using a more permissive blocking rule (this results in more total inventor careers being identified). The clusters reported in the upper-bound disambiguation are strict subsets of those reported in the lower-bound (in other words, the upper-bound careers are either the exact same career as the lower-bound, or splits of the lower-bound careers). We recommend that investigators either run both sets of estimates, or manually verify the accuracy, when possible, or justify the more skeptical selection on theoretical grounds.

4.1 Estimating accuracy

In order to estimate the error rates in the two clustering solutions, we compared our efforts to a manually curated dataset (Gu et al., 2008).¹³ The original dataset was a sample of 95 US

¹³ Jerry Marschke, lead investigator on the original development of the dataset, generously agreed to our usage and to post the results as well.

inventors (1332 inventor-patent instances) drawn from the engineering and biochemistry fields, with current or previous academic affiliations. As these are eminent academics, this database oversamples prolific inventors (though this is not uncommon amongst hand curated datasets used for learning or testing purposes). The patents within the benchmark dataset were first identified from inventors' CVs. We updated these Gu et al. (2008) patent lists, and then repeatedly attempted to contact all inventors in the dataset, via email and then phone, in order to validate our disambiguation of their patents. We also cross-checked our results with online resources and human pattern recognition. We had a total of 43 confirmed responses and 52 unconfirmed responses (we differentiate between confirmed and unconfirmed in the posted file). The benchmark dataset contains the patent history of these 95 US-based academic inventors.

For each inventor in this standard we identified their split records (that failed to map to his/her largest cluster). The total number of split records divided by the total number of records in the standard yields our splitting statistic. Similarly, for each cluster in the standard, we identified lumped records (that did not belong in the largest sub-cluster by a single inventor in the standard.) The total number of lumped records divided by the total number of records in the standard yields our lumping statistic.

Based on this curated dataset, splitting and lumping errors are 3.19% and 1.50% of records for the lower bound, and 3.57% and 1.50% for the upper bound. Nearly all the lumping errors are attributable to a few very common names, namely David Johnson, Eric Anderson and Stephen Smith.

4.2 Inventor Cluster Confidence Scores

To aid researchers in deciding which disambiguation to use for their particular application, we have developed a set of descriptive statistics that describe our confidence in the reported inventor clusters. These statistics are calculated at the level of the lower-bound cluster, allowing researchers to make the decision of which disambiguation to trust at this very granular level.

As described above, the threshold process which converts the full set of inventor-patent pair match probabilities to a cluster throws away a substantial amount of information. This procedure effectively rounds all match probabilities for records within the same cluster to 1 while rounding all match probabilities for records in different clusters to zero, allowing the reported disambiguation to diverge from what the data support in two ways. First, match probabilities that are relatively low can be rounded up as a side effect of the clustering process, resulting in some records within the same cluster that have very low similarity. Second, match probabilities that are relatively high can be rounded down because they do not meet the match threshold, resulting in records that have real similarity being split into different blocks.

To measure how significantly these errors affect clustering, we calculate the *within-cluster density* and the *out-of-cluster density*, respectively. The within-cluster density is the average match probability between every pair of records within a cluster. A high within-cluster density indicates that the data strongly support the clustering, while a low value suggests the cluster is held together by spurious association. The out-of-cluster density, on the other hand, is the average match probability between every pair of records in a block that were not assigned to that cluster. A low score here indicates that the records were correctly split into multiple clusters, whereas a high score indicates that the clustering may be too granular, as a large amount of similarity was left unrecognized by the clustering. To make this discussion more intuitive, we deal with *out-of-cluster sparsity* (one minus the out-of-cluster density) instead so that we can say that a high score for both of these statistics indicates high confidence.

For our confidence statistics, we calculated a within-cluster density for each lower-bound cluster. Within each lower-bound cluster we also calculated an average within-cluster density for the upper-bound clusters and the out-of-cluster sparsity that resulted from splitting the lower-bound cluster into the upper-bound cluster. The first score can be used to gauge our confidence in the lower-bound clusters, and the other two can be used to gauge our confidence in the upper-bound data.

When choosing which disambiguation to use for a particular application, researchers can begin by choosing the lower-bound clusters that correspond to their area of interest, and checking the three confidence statistics. The researcher should compare the upper- and lower-bound density measures – if there is little difference, the lower-bound is likely safe to use. If there is a large difference, the researcher should check the out-of-cluster sparsity of the upper-bound blocks to see how much splitting accuracy was sacrificed to improve lumping performance when splitting the larger cluster into smaller clumps. If the sparsity of the upper-bound blocks is high, then it is likely safe to use the upper-bound blocks. In cases where all three confidence measures are low, the researcher might consider performing a manual disambiguation on the subset of interest using the lower-bound cluster as a starting point.

5. Disambiguated data and illustrative applications

5.1 Descriptive Statistics

Figure 5 illustrates year over year statistics for the number of patents and unique inventors, for the lower disambiguation results.¹⁴ The number of unique inventors closely tracks the number of patents as might be expected, and there appears to be more unique inventors than patents. Figure

¹⁴ The upper and lower bound sets are very close. Given the closeness, the trend lines overlap and there is little visual difference, therefore we graph only the lower line.

6 shows the number of patents per unique inventor, based on the lower disambiguation. Over 85% of the total inventor population has 5 or fewer patents, while less than 1% have 50 or more.

Figure 5: Number of patents and unique inventors from lower bound disambiguation. Early data are less accurate due to lack of inventor history before 1975.

Figure 6: Number of patents per unique inventor

5.2 Inventor networks

Disambiguation of the inventor record enables research into co-authorship networks of inventors. A variety of questions can be investigated, for example, the impact of social structure on individual creativity (Fleming et al. 2007), knowledge diffusion (Singh 2005), and regional dynamics (Breschi and Lissoni 2009). Bibliometric records of co-authorship networks provide both advantages and disadvantages in the study of social structure. If the data are large enough, researchers can sample to minimize spurious significance caused by lack of independence

between proximal nodes. Bibliometric networks are typically observed over time, and hence do not need to be repeatedly sampled. If the structures are large and continuous, researchers can avoid cutting networks at arbitrary points. Bibliometric networks in general are much cheaper to build than survey networks, though they cannot capture the same richness of direct observation or survey. They avoid response bias, in that all individuals are observed, though on the other hand, they inherently suffer from selection bias, in that unsuccessful attempts to patent or publish remain unobserved.

We provide a sample of social network measures, within three-year blocks, starting in 1975. They include degree (the number of number of unique co-authors in a three year period), eigenvector and node centrality (Bonacich 1991), and clustering coefficient (Watts and Strogatz 1998). The size of the inventor's component is also included, the number of inventors in that three-year period that can be reached through a co-author, and the ranking of this component, in the same three-year period, against all other components in that period. The Harvard DataVerse Network (DVN) interface allows researchers to subset the networks, based on a number of criteria such as name, time, or technology.

5.3 Inventor mobility movies

Much research has used patent records to study inventor mobility, often in the study of regional dynamics (Almeida and Kogut 1999, Agrawal et al. 2006; Breschi and Lissoni 2009, Marx et al. 2009). Most of this research has relied on manual or ad hoc disambiguation and not considered across-region mobility. Automated disambiguation of entire patent records enables study – and visualization – of cross-regional mobility. Figures 7-10 illustrate the emigration and immigration of the U.S. state of Michigan, in 1982, 1987, and 1987, respectively, and emigration into California, at the height of the technology boom in 2000.¹⁵ Interestingly, early years illustrate a net loss of inventors from California, possibly due to decreased defense spending. The interested reader is encouraged to investigate all years of mobility.

Figures 7 and 8 illustrate a noticeable increase in emigration from Michigan, comparing 1982 to 1987. Figure 9 illustrates how this emigration was not balanced by immigration. Marx et al. (2012) establish that the emigration increase is partially caused by the inadvertent enforcement of noncompete covenants starting in 1985. Their identification relied on a differences-in-differences methodology, which compared emigration from Michigan to emigration from other control states that prohibited enforcement of noncompetes over the entire time period of study, from 1975-1996 (these pictures are anecdotal – we urge the interested reader to independently

¹⁵ Movies for all years since 1975, for these states and other states, can be viewed, along with a moving histogram of origin or destination states, at http://atticus.berkeley.edu/guanchengli/arcc/index_w.php. See also: <http://funginstitute.berkeley.edu/tools-and-data>.

assess the comprehensive diff-in-diffs models). Marx et al. also provide corroborating cross sectional evidence for all U.S. states, from 1975-2005. In total, these analyses relied on the analysis of 540,780 careers; this would have been impossible without an automated and reasonably accurate disambiguation across the entire patent record.

Figure 7: Emigration of patented inventors from Michigan in 1982.

Figure 8: Emigration of patented inventors from Michigan in 1987. Note the greater total amount of emigration (the right hand tail of the distribution represents one inventor in both cases), along with the greater proportion to California and Washington, states that do not enforce noncompete covenants. For comprehensive statistical evidence of a “brain-drain,” please Marx et al. 2012.

Figure 9: Immigration of patented inventors into Michigan in 1987. Note the stark contrast with emigration (Figure 8); 1987 was not an anomaly, for example, 1981 had no immigration. This reflects the general economic malaise of the state, during the contraction of the automobile industry.

Figure 10: Immigration of patented inventors into California in 2000, at height of technology boom.

5.4 Linkage to PubMed

Disambiguation of careers from bibliometric databases enables a variety of career linkages across other databases. Such integration could enable the study of the impact of science funding, by linking grants to papers, papers to patents, and patents to economic outcomes. To illustrate a first step in realizing this research opportunity, Figure 11 provides an illustration of the Authority Database at the University of Illinois Urbana Champagne. Given an inventor, scientist, or Principal Investigator, a researcher can look for their other work products. The screenshot illustrates Robert Langer, an exceptionally prolific scientist and inventor at the Massachusetts Institute of Technology. Details of the PubMed disambiguation can be found in Torvik and Smalheiser (2009) and details on the linkage between patents and papers can be found on the Torvik group website.¹⁶

6. Conclusion

Many scholars of innovation have begun to disambiguate patent records (Fleming and Juda 2004; Singh 2005; Trajtenberg et al., 2006; Raffo and Lhuillery 2009; Carayol and Cassi, 2009; Lai et al., 2009; Pezzoni et al., 2012). We provide a disambiguation of the U.S. patent record and make our code and algorithms public, in hopes of eliciting public use, comment, and improvement. In contrast to previous ad hoc methods, this approach drew from computer and information science and applied a Bayesian machine learning approach. The work provides public databases and tools that enable identification of co-authorship networks in the USPTO database, and an application of the data by illustrating inventor mobility into and out of Michigan, California, and other states.

6.1 Caveats and Planned Improvements

Perhaps the most important next challenge in disambiguation is to accommodate ethnic and geographical differences; we have adopted a U.S. centric approach, and not surprisingly, European names consequently work best. Chinese, Korean and Taiwanese generally do not have middle name although a western style “middle name” can still be extracted. Their first names can be reset to the concatenation of extracted first name and extracted last name; their last name the same; their middle names to the concatenation of modified first name and last name. For Japanese names, however, the raw data generally do not contain a middle name and the names are usually very similar in their English spellings. Related to these challenges, some first and last names, even non-Asian names, can be switched in the input data.

While our work is based mostly on the 2005 Author-ity model (Torvik et al. 2005), more recent work in 2009 (Torvik and Smalheiser 2009) provides a number of suggestions for more rigorously setting parameters like block priors and the weighting coefficient in triplet correction, and for handling correlations between fields in the data (e.g. living in Korea and working for Samsung) that can bias disambiguation results. Other potential improvements include: accounting for firm size in the assignee comparison algorithm, incorporating population density as an additional factor for the location comparison algorithm, and using additional data fields (essentially expanding the profile feature set), such as comparisons of titles and abstracts or patent lawyers and prior art citations (Tang and Walsh, 2010). Also, existing data fields such as technology sub-classes and co-authors could be examined in finer detail. Ideally, scholars might choose from amongst multiple disambiguated datasets, each of which would avoid using the variable of interest for disambiguation (for example, if a researcher was studying inventor mobility across firms, the database would ideally not use assignees in disambiguation, for an example of this approach based on simulation, see Pezzoni et al. 2012). Much work remains; hopefully this disambiguation and the public data it creates can provide the foundation for future improvements and increased research productivity.

Appendix 1

Further USPTO XML file clarification

This Appendix is based upon correspondences with the USPTO and further clarifies the XML patent file. The language used here was provided by the USPTO.

Appendix 1 Table 1 - U.S. Patent Grant and Published Applications Document Numbers:

Patent Grant Patent Number

- Design Patents
 - Position 1 – A constant “D” identifying the granted document as a Design Patent.
 - Positions 2-8 – Seven-position numeric, right justified, with a leading zero.
- SIR Patents
 - Position 1 – A constant “H” identifying the granted document as a Statutory Invention Registration (SIR).
 - Positions 2-8 – Seven-position numeric, right justified, with a leading zero.
- Plant Patents
 - Positions 1-2 – A constant “PP” identifying the granted document as a Plant Patent.
 - Positions 3-8 – Six-position numeric, right justified, with a leading zero.
- Reissue Patents
 - Position 1-2 – A constant “RE” identifying the granted document as a Reissue Patent.
 - Positions 3-8 – Six-position numeric, right justified, with a leading zero.
- Utility Patents
 - Positions 1-8 – Eight-position numeric, right justified, with a leading zero.
- X-Series
 - Patents issued between July 31, 1790 and July 4, 1836. They were not originally numbered, but have since been assigned numbers in the sequence in which they were issued
 - Positions 1-8 – Eight-position, right justified, with a leading “X”.

Appendix 1 Table 2 - U.S. Patent Grants and Patent Published Applications

Kind Codes

Note: The following 2-position kind codes will be present in the XML <kind> tags of Red Book and Yellow Book. These 2-positions kind codes will also be present on the printed documents

with the following exceptions: Reissues will contain a single position “E”, SIR documents will contain a single position “H”, and Designs will contain a single position “S”.

- A1 - Utility Patent Grant issued prior to January 2, 2001.
- A1 - Utility Patent Application published on or after January 2, 2001
- A2 - Second or subsequent publication of a Utility Patent Application
- A9 - Correction published Utility Patent Application
- Bn - Reexamination Certificate issued prior to January 2, 2001.
 - NOTE: “n” represents a value 1 through 9.
- B1 - Utility Patent Grant (no published application) issued on or after January 2, 2001.
- B2 - Utility Patent Grant (with a published application) issued on or after January 2, 2001
- Cn - Reexamination Certificate issued on or after January 2, 2001.
 - NOTE: “n” Represents a value 1 through 9 denoting the publication level.
- E1 - Reissue Patent
- H1 - Statutory Invention Registration (SIR) Patent Documents.
 - Note: SIR documents began with the December 3, 1985 issue
- I1 - “X” Patents issued from July 31, 1790 to July 13, 1836
- I2 - “X” Reissue Patents issued from July 31, 1790 to July 4, 1836
- I3 - Additional Improvements – Patents issued between 1838 and 1861.
- I4 - Defensive Publication – Documents issued from Nov 5, 1968 through May 5, 1987
- I5 - Trial Voluntary Protest Program (TVPP) Patent Documents
- NP - Non-Patent Literature
- P1 - Plant Patent Grant issued prior to January 2, 2001
- P1 - Plant Patent Application published on or after January 2, 2001
- P2 - Plant Patent Grant (no published application) issued on or after January 2, 2001
- P3 - Plant Patent Grant (with a published application) issued on or after January 2, 2001
- P4 - Second or subsequent publication of a Plant Patent Application
- P9 - Correction publication of a Plant Patent Application
- S1 - Design Patent

Appendix 1 Table 3 - U.S. Application Series Codes

Code:	Filing Dates:
02	Filed prior to January 1, 1948
03	January 1, 1948 through December 31, 1959
04	January 1, 1960 through December 31, 1969
05	January 1, 1970 through December 31, 1978
06	January 1, 1979 through December 31, 1986
07	January 1, 1987 through January 21, 1993
08	January 22, 1993 through January 20, 1998

09	January 21, 1998 through October 23, 2001
10	October 24, 2001 through November 30, 2004
11	December 1, 2004 through December 5, 2007
12	December 6, 2007 through Current

Design Patents

Code:	Filing Dates:
07	Filed prior to October 1, 1992
29	Filed after October 1, 1992

Note: The Design Series Coded “29” is present in the XML data as “29” and is displayed as a “D” on Patent on the Web.

Appendix 1 Table 4 - U.S. Patent Classifications

Class

- A 3-position alphanumeric field right justified with leading spaces.
- Design Patents
 - The first position will contain a “D”.
 - Positions 2 and 3, right justified, with a leading space when required for a single digit class.
- Plant Patents
 - Positions 1-3 will contain a “PLT”
- All Other Patents
 - Three alphanumeric positions, right justified, with leading spaces

Sub-Class

- Three alphanumeric positions, right justified with leading spaces, and, if present, one to three positions to the right of the decimal point (assumed decimal in the Red Book XML), left justified.
- A digest entry as a sub-class would appear as follows:
 - Three positions containing “DIG”, followed by one to three alphanumeric positions, left justified.

Appendix 1 Table 5: Assignee Type Categories

- 01 Unassigned
- 02 United States company or corporation

- 03 Foreign company or corporation
- 04 United States individual
- 05 Foreign individual
- 06 U.S. Federal government
- 07 Foreign government
- 08 U.S. county government
- 09 U.S. state government

Categories 10-16 are currently unexplained by the USPTO. Source:

<http://www.uspto.gov/web/offices/ac/ido/oeip/sgml/st32/redbook/pap-v15-2001-01-31/dtdelem/assignee-type.html>.

Appendix 2 Data distribution

All the data used in and resulting from the disambiguation is public and freely available through the Harvard Dataverse Network. Supporting datasets contribute either to creating the consolidated inventor results dataset or enhance the algorithm. Other datasets derived from parsing USPTO patent data are included for reference. Due to the portability of the file type, we now employ Sqlite3 for database files. Results datasets are presented in both Sqlite3 and .csv formats.

The Harvard Patent Dataverse provides a platform for providing access to the various datasets described in this paper. An inventory list summarizing the details of the material available follows:

1. Raw Patent Datasets consisting of individual zipped directories containing parsed USPTO patent data in sqlite3 and .csv formats.
2. Network datasets consisting of individual subsettable GraphML files for every three years from 1975-2010, upper and lower bound results. Networks consist of inventors as nodes and patents as links. 26 files in all.
3. Results datasets consisting of individual subsettable tabular datasets for every three years from 1975-2010, upper and lower bound results. Includes inventor and patent data, and calculated variables. 24 files in all.
4. Full disambiguation results including individual zipped directory containing sqlite3 and .csv files for upper and lower bound result.
5. Documentation including a whitepaper on data techniques and description of disambiguation algorithm, and a benchmark dataset used for results analysis.

Appendix 3 Software and computation

We wrote a generic disambiguation engine in C/C++, in order to provide developers with a modular and computationally efficient way to specify any disambiguation strategy on any database. Quadratic programming for the interpolation, the extrapolation and the enforcement of monotonicity of similarity profiles is performed using IBM CPLEX. It takes about three hours to concurrently complete the adjustment of the six dimensional similarity profiles on an 8CPU 24GB workstation. The original code base is currently available online at http://www.github.com/patentnetwork/CPP_Disambiguation. Revised and updated code is available at <https://github.com/funginstitute/downloads>. We invite community members to use this implementation to write their own disambiguation of the patent database.
